It is well known that the entanglement of a quantum state is invariant under local unitary transformations. This rule dictates, for example, that the entanglement of internal degrees of freedom of a photon remain invariant during free-space propagation. Here, we outline a scenario in which this paradigm does not hold. Using local Bell states engineered from classical vector vortex beams with non-separable degrees of freedom, so-called classically entangled states, we demonstrate that the entanglement evolves during propagation, oscillating between maximally entangled (purely vector) and product states (purely scalar). We outline the spin-orbit interaction behind these novel propagation dynamics and confirm the results experimentally, demonstrating spin-orbit coupling in paraxial beams. This demonstration highlights a hitherto unnoticed property of classical entanglement and simultaneously offers a device for the on-demand delivery of vector states to targets, e.g., for dynamic laser materials processing, switchable resolution within STED systems, and a tractor beam for entanglement.

Keywords: complex light fields, classical entanglement, entanglement oscillation, spin-orbit coupling.

INTRODUCTION

Under local unitary operations, e.g., when propagating through a unitary channel, the degree of entanglement does not change. This finding is true for both non-local entanglement, i.e., light fields (including single photon, multi-photons, or coherent light) that simultaneously exist in physically separated locations, and for local entanglement, i.e., between the internal degrees of freedom of a single photon. Recently, it has become of interest to study the latter and to mimic the former using vector states of classical light1-10. This approach is possible because the central feature of entanglement, non-separability, is not limited to quantum systems: classical vector beams are likewise non-separable, e.g., in their polarization and spatial modes. However, whether such fields can be called "classically entangled" is an open question11, in practice, this property has been exploited for real-time quantum error correction12-16, laser materials processing17-19, and metrology20-22. Additionally, in imaging23-26, where tightly focused radially polarized fields are known to produce the narrowest spot size27-30, classically entangled light fields allow super resolution microscopy techniques31,32.

Here, we demonstrate that entanglement can evolve during propagation in free space using classically entangled vector vortex beams, which are non-separable in orbital and spin angular momentum. We engineer superpositions of these beams to prove the dynamic change of entanglement upon propagation through spin-orbit (SO) coupling. Such SO coupling33 has been observed through the spin-Hall effect of light at planar interfaces, by non-paraxial light (tightly focused by high-numerical aperture lenses), and with paraxial light in anisotropic and inhomogeneous structures, for example, using geometric phase34. Here, we show that it is possible with paraxial light in free-space. Through this SO coupling, we demonstrate entanglement beating from fully entangled (completely non-separable) to no entanglement (fully separable), and by a phase adjustment, we achieve the possible transport of entanglement, which is reminiscent of tractor beams for particle transport35-38. This realization may open new avenues in quantum and classical communication as well as in improved materials processing (where vector beams and scalar polarized beams are crucial) and enhanced switchable imaging in STED microscopy.

MATERIALS AND METHODS

Concept. Consider a vector beam that is composed of a superposition of two orthogonally polarized Laguerre-Gaussian modes \(LG^\ell_p (x, y)\) given by

\[
\Psi_{VB} = \frac{1}{\sqrt{2}} \left[LG^\ell_p \left| R \right\rangle + e^{-i\alpha} LG^{\ell_p} \left| L \right\rangle \right] e^{i\phi z z},
\]

where we assume a propagation in the \(\pm z\)-direction, approximated by the factor \(e^{i\phi z z}\), where \(\kappa = (k_x, k_y, k_z)\) is the wave vector expressed in terms of the wavelength \(\lambda\), as \(k = 2\pi / \lambda\). The kets \(\left| R \right\rangle\) and \(\left| L \right\rangle\) represent the unit vector of right- and left-handed circular polarization states, respectively, and \(\alpha\) defines the phase relation between the two states. The indices \(\ell\) and \(p\) denote the azimuthal and radial degrees of freedom, respectively, the former being related to the orbital angular momentum (OAM) of the Laguerre-Gaussian beam. In the following description, we will restrict ourselves to the case in which \(\ell_1 = -\ell_2 = \ell\) and \(p_1 = p_2 = p\), but it can be extended to other cases. Equation (1) can be conveniently written as39.

© 2018 Changchun Institute of Optics, Fine Mechanics and Physics (CIOMP), Chinese Academy of Sciences (CAS). All rights reserved.
\[ |\Psi\rangle = \sqrt{a} |u_{R}\rangle |R\rangle + \sqrt{1-a} |u_{L}\rangle |L\rangle \]  

(2)

where \[L_{G_{p}}^{*}\cdot e^{i(za\alpha k_{z}z)} = [L_{G_{p}}^{*}\cdot e^{i\lambda_{z}k_{z}}] \]

are represented by the ket \[|u_{R,L}\rangle\] and the relative weightings of \[|u_{R}\rangle\]

and \[|u_{L}\rangle\] by \[a\]. Moreover, \[|u_{R,L}\rangle\] satisfies the normalization condition \[\langle u_{R,L} | u_{R,L} \rangle = 0\].

The degree of non-separability (classical entanglement) \[E(|\Psi\rangle) \in [0,1]\] of a vector field as defined by Eq. (2) can be computed using tools from quantum mechanics. Here, we consider the entanglement entropy, originally derived for quantum states \[40,41\] and later extended to classical non-separable states \[39\] as

\[ E(|\Psi\rangle) = -[a \cdot \log_{2}(a) + (1-a) \cdot \log_{2}(1-a)] \]  

(3)

Consequently, if we analyze a vector beam \[|\Psi_{VB}\rangle\]

under a unitary transformation, i.e., propagation in free space along the \(+z\) -direction (Eq. (1)), where \[a = 1/2\]

for all \(z\) values, we observe a spatially invariant degree of entanglement \[E(|\Psi_{VB}\rangle) = 1\].

Remarkably, we can engineer a light field \[|\Psi(x,y,z)\rangle\]

with a \(z\)-dependent degree of entanglement \[E(|\Psi\rangle, z)\]

by combining two orthogonal vector beams \[|\Psi_{VB}^{+}\rangle\] and \[|\Psi_{VB}^{-}\rangle\], coaxially propagating in opposite directions, as illustrated in Fig. 1(a). For example, these orthogonal fields can be generated by setting \[\alpha_{VB} = 0\]

and \[\alpha_{VB} = \pi/2\] in Eq. (1), namely,

\[ |\Psi_{VB}^{+}\rangle = \frac{1}{\sqrt{2}} \left( |L_{G_{p}}^{+}\rangle |R\rangle + |L_{G_{p}}^{-}\rangle |L\rangle \right) e^{i k_{z} z} \]  

(4)

and

\[ |\Psi_{VB}^{-}\rangle = \frac{1}{\sqrt{2}} \left( e^{i \pi / 2} |L_{G_{p}}^{+}\rangle |R\rangle + e^{-i \pi / 2} |L_{G_{p}}^{-}\rangle |L\rangle \right) e^{i k_{z} z} \]  

(5)

with a phase distribution as a function of \(z\) as shown in Fig. 1(b), top and bottom, respectively, for the case \(\ell = 1, p = 0\). The normalized field that results from such a superposition takes the form

\[ |\Psi_{VB}\rangle = \frac{1}{2} \left( e^{i k_{z} z} + e^{-i k_{z} z} \right) |L_{G_{p}}^{+}\rangle |R\rangle + \frac{1}{2} \left( e^{-i k_{z} z} - e^{i k_{z} z} \right) |L_{G_{p}}^{-}\rangle |L\rangle \]  

(6)

whose polarization evolution upon propagation for the regarded example is shown in Figs. 1(c) and (d), respectively. Here, (c) includes the change in the relative phase between the superimposed beams, which represents the origin of the resultant \(z\)-variant polarization structure. The new engineered state \[|\Psi\rangle\]

undergoes an oscillatory transition between fully vector and fully scalar modes of light, which can be described by the SO interaction \[33\]. The total angular momentum of our field always satisfies \(J_{z} = 0\) (for superposition beams constructed from the \(\ell = \pm 1\) subspace) but with oscillatory spin and orbit components that vary as \[S_{z} \propto \sin(2k_{z}z)\] and \[L_{z} \propto -\left(\sin(2k_{z}z)\right)\], respectively. As a result of the out-of-phase oscillation for opposite helicities, as the OAM component increases, the spin component decreases concomitantly to conserve the total angular momentum (see Supplementary Information).

This variation between the scalar and vector modes manifests itself through a change in the degree of entanglement, as defined by Eq. (3), which for the new light field \[|\Psi\rangle\] takes the form

\[ E(|\Psi\rangle, z) = 1 - \frac{1}{2} \left[ 1 + \sin(2k_{z}z) \right] \cdot \log_{2} \left[ 1 + \sin(2k_{z}z) \right] - \frac{1}{2} \left[ 1 - \sin(2k_{z}z) \right] \cdot \log_{2} \left[ 1 - \sin(2k_{z}z) \right] \]  

(7)

(details with respect to the calculations can be found within the Supplementary Information). Thus, the state undergoes a periodic variation in the degree of entanglement as a function of \(z\), as illustrated in Fig. 1(d), bottom, while the intensity profile remains constant. Full entanglement, i.e., maximal non-separability \([E(|\Psi\rangle, z) = 1]\), is achieved at \(z = n \lambda / 4, n \in \mathbb{N}\), whereas non-entanglement, i.e., complete separability \([E(|\Psi\rangle, z) = 0]\), is observed at \(z = (2n+1) \lambda / 8, n \in \mathbb{N}\). Note that space-variant entanglement of the form \[E(|\Psi\rangle, z)\] can be realized by any OAM subspace \(\ell\) by the superposition of orthogonal vector fields \[|\Psi_{VB}^{+}\rangle\] and \[|\Psi_{VB}^{-}\rangle\], as long as they carry the same radial order \(p_{1,2}(V_{B_{1,2}}) = p\). In contrast, if we superimpose two counter-propagating scalar modes of opposite helicity and orthogonal polarization, the degree of entanglement will remain constant (see Supplementary Information).

This unique property of the field \[|\Psi\rangle\] provides a means to facilitate the transport of a chosen degree of entanglement across arbitrary distances, by simply applying a phase adjustment \(\phi\), which is reminiscent of tractor beams \[35-38\]. To illustrate this approach, we can replace the propagation factor in Eq. (1) by the factor \[e^{i (k_{z} z + \phi)}\]. In this way, the maximum degree of entanglement \([E_{\text{max}}(|\Psi\rangle) = 1]\), for example, can be...
transported to a position $z_{\text{max}}$ according to the expression

$$z_{\text{max}}(\varphi) = \frac{\lambda}{4} \left( m - \frac{2\varphi}{\pi} \right), \quad m \in \mathbb{Z}. \quad (8)$$

This means that any chosen state can be conveyed to a specific position in space, along the propagation axis, by simply adjusting the phase $\varphi$. Moreover, by applying a time-dependent phase shift $\varphi(t)$, it is possible to impart a time-dependent movement of a regarded maximum with an axial velocity given by

$$v_{\text{max}}(t) = -\frac{\lambda}{2\pi} \frac{\partial\varphi(t)}{\partial t}. \quad (9)$$

**Experimental details.** A simple method to generate a light field $|\Psi\rangle$ with local entanglement beating is via an interferometric approach. An exemplary system is sketched in Fig. 2(a). By combining a Sagnac interferometer with a half-wave plate (diagonally oriented), a single incident vector beam, e.g., radially polarized, can be used for the generation of a standing wave according to Eqs. (4-6), whose local degree of entanglement $E$ oscillates upon propagation. Note that in each arm of the interferometer, counter-propagating (green arrows) vector modes of orthogonal polarization will give rise to a classically entangled standing wave, as indicated by a red curve in one of the arms.

Even if this approach of counter-propagating beams is very intuitive, the investigation of the light field $|\Psi\rangle$ would be challenging because any measuring device inserted in the path would destroy the oscillatory behavior of the light field $|\Psi\rangle$. Here, we propose an alternative approach that allows us to quantify the spatially varying degree of entanglement. This approach is based on the engineered superposition of co-propagating orthogonally polarized vector modes, as visualized in Fig. 2(b). By applying digital propagation, we can artificially counter-propagate the two modes (red arrows), which physically co-propagate in the same direction (green arrows), enabling us to investigate the light field $|\Psi\rangle$ along the beam path.

The digital propagation of a light field $U(\vec{r}, z)$ propagating in the $z$ direction is based on the angular spectrum technique, according to which $U(\vec{r}, z) = F^{-1}\{F[U(\vec{r}, 0)] e^{i k z}\}$, where $\vec{r} = (x, y, z)$ are the coordinates in real space, and $F$ and $F^{-1}$ are the Fourier and inverse Fourier transforms, respectively. Next, by the application of Fourier holograms in combination with a phase shift $\pm k/z$, encoded on a spatial light modulator (SLM), we were able to digitally propagate a light field in the $\pm z$ direction. To independently control the phase shift of each vector mode, to artificially generate counter-propagating vector modes, we developed a new method that facilitates the generation of any vector beam using a multiplexing approach enabled by an SLM. This method allows not only simultaneous generation of multiple vector modes but also their independent manipulation, such as digital propagation.

The idea behind our method is to encode a superposition of different holograms, each with a different spatial carrier frequency (blazed grating), on a single SLM. Thus, each beam is sent to different transverse positions in space, which allows manipulation of their polarization independently, as required for vector beam generation. For example, to generate a radially polarized vector beam, we multiplexed the corresponding holograms to create two helical LG beams with opposite topological charges ($\ell = \pm 1$) on the SLM. A half-wave plate placed in the path of one beam changes its polarization from horizontal to vertical. Both beams were then recombined and passed through a quarter-wave plate to change the horizontal and vertical polarizations into left- and right-circular polarizations, respectively, thus generating the desired vector beam.

In the present case, where we realized a superposition of two cylindrical vector beams $V_{B,2}$ (see Fig. 2(c), red box, and (d)), four vortex beams were multiplexed in the SLM (SLM$_1$); Fourier holograms, manipulated accordingly and (counter-) propagated digitally (Fourier relation between SLM$_1$ and SLM$_2$ by lens $L_1$) to investigate the desired field $|\Psi\rangle$ within the observation plane (SLM$_2$). In this way, the detection system can remain static while the created vector beams artificially propagate in opposite directions. Beyond this, digital propagation, encoded on the SLM as a phase shift $\varphi$, facilitates the realization of a chosen degree of entanglement at the observation plane, which is similar to the case of tractor beams.

**Theory of entanglement entropy.** For the analysis of the light field $|\Psi\rangle$, we determined the degree of classical entanglement, i.e., the degree of non-separability, in different $(x, y)$-planes. An appropriate tool for this concern is the quantum mechanics entanglement entropy.

$$E = \frac{h(1 + s)}{2}, \quad (10)$$

with $h(r) = -r \log_2(r) - (1-r) \log_2(1-r)$. Here, $s$ is the length of the Bloch vector, given by $s = \left( \sum \sigma_i \right)^{1/2}$, where $i = \{1,2,3\}$, where $\sigma_i$ are the expectation values of the Pauli operators. These values are obtained by a set of 12 normalized, on-axis intensity measurements or six identical measurements for two different basis states.

We chose circular polarization as a basis. As a consequence, the projection measurements are given by two modes that carry the OAM of topological charge $\ell$ and $-\ell$, in addition to four superposition states represented by $e^{i\varphi} + e^{-i\varphi}$ and $e^{i\varphi} - e^{-i\varphi}$ with $\varphi = \{0, \pi/2, \pi, \ell, 3\pi/2, 2\ell\}$ ($\phi$: azimuthal angle in polar coordinates). In the case at hand, we investigate the
vector modes of first order (cf. Results and Discussion section), and hence, the projection measurements are performed for \( \ell = 1 \).

According to Table I, the expectation values \( \langle \sigma_i \rangle \) are calculated from

\[
\begin{align*}
\langle \sigma_1 \rangle &= (I_{13} + I_{23}) - (I_{15} + I_{25}), \\
\langle \sigma_2 \rangle &= (I_{14} + I_{24}) - (I_{16} + I_{26}), \\
\langle \sigma_3 \rangle &= (I_{11} + I_{21}) - (I_{12} + I_{22}),
\end{align*}
\]

(11) - (13)

To determine the entanglement entropy \( E \) experimentally, we measure the on-axis intensity values \( I_{uv} \) with \( u, v \in \{1,2,3\} \), as indicated in Fig. 2(c), blue box, and (e). Therefore, polarization projections are performed by the use of a quarter-wave plate \((\lambda/4)\) set to \( \pm 45^\circ \) in combination with a polarization-sensitive spatial light modulator (SLM2) and OAM projections by a phase pattern on this modulator. The respective phase pattern carries the information of all six OAM projections, in which each of them is assigned to another spatial carrier frequency\(^{46}\). The application of this demultiplexing hologram results in six outputs on the CCD camera (Fig. 2(e)) positioned in Fourier relation with the observation plane (SLM2) by a lens (L2), which enables a single-shot measurement for each polarization basis.

For the entanglement entropy analysis in different \((x, y)\)-planes of the light field, artificial propagation in the \( z \)-direction is applied. Further, the intensities \( I_{uv} \) for different planes are normalized by \( I_{11} + I_{12} + I_{21} + I_{22} \) for left- and right-circular polarization basis.

**RESULTS AND DISCUSSION**

To verify that the field \(|\Psi\rangle\) follows the entanglement dynamics predicted by Eq. (7), we experimentally generated and superimposed two orthogonal vector beams (according to Eqs. (4) and (5)), using the setup shown in Fig. 2(c), as indicated by the red box. For simplicity but without the loss of generality, we chose first-order radially and azimuthally polarized modes with \( \ell = 1 \) and \( p = 0 \). Magnifications of the different sections of the generation process are shown in (d). The desired light field \(|\Psi\rangle\) for a specific \( z \)-position is realized in the Fourier plane (SLM2, observation plane) of SLM1.

The artificially generated field \(|\Psi\rangle\) can be separated into its \(|R\rangle\) and \(|L\rangle\) parts, with each including two counter-propagating LG modes of the same helicity. For each polarization, one mode propagates in the \( +z \)-direction, and the other propagates in the \(-z\)-direction, which is achieved through digital propagation enabled by SLM1. The digital propagation was encoded as \( e^{i\phi(z, z + \varphi)} \), in which we chose \( \varphi \) to be a discrete phase offset of \(-\pi/4\). Using a CCD camera positioned in the observation plane, we recorded the intensity profile of the \(|R\rangle\) and \(|L\rangle\) components separately by shutting beams 3 and 4 or 1 and 2 (cf. Fig. 2(c), (d)), respectively. The results are shown in Fig. 3. In Fig. 3(b), we show the simulated transverse intensity profile of \(|\Psi\rangle\) when a horizontally aligned polarizer is positioned in front of the CCD, thus reflecting the polarization distribution illustrated in (a) and Fig.1. The normalized intensity profiles for the \(|R\rangle\) (beam 1+2) and \(|L\rangle\) (beam 3+4) polarization components are shown in Fig. 3(c) and (d), respectively, for the different positions \( k \_z + \varphi \in [0, \pi] \) (arrow at the bottom). For both the \(|R\rangle\) and \(|L\rangle\) parts, we observe a sinusoidal variation in the intensity that depended on \( k \_z + \varphi \), which represented a longitudinal interference pattern of included beams. Furthermore, the variation in intensity for \(|R\rangle\) and \(|L\rangle\) is out of phase, i.e., the \(|R\rangle\) components carry maximum intensity while the \(|L\rangle\) parts are at minimum, and vice versa. This behavior is attributed to the phase shift \( \varphi_{\text{VB}} \), which is used to create orthogonally polarized vector beams (cf. Eq. (14)). Moreover, these counter-fluctuating intensities evince the variation between pure vector and pure scalar states for \(|\Psi\rangle\): If the \(|R\rangle\) \((|L\rangle\)\) polarized components are at a maximum, while the \(|L\rangle\) \((|R\rangle\)\) parts disappear, then \(|\Psi\rangle\) is represented solely by the \(|R\rangle\) \((|L\rangle\)\) components, and thus, the light field is purely scalar with \( E(\Psi, z) = 0 \), \( k \_z + \varphi = \{0, \pi/2, \pi\} \). In contrast, if the \(|R\rangle\) and \(|L\rangle\) parts are of equal intensity, then \(|\Psi\rangle\) is a pure vector mode with \( E(\Psi, z) = 1 \), \( k \_z + \varphi = \{\pi/4, 3\pi/4\} \). Between these extreme cases, a smooth transition is found (cf. (b)).

**Entanglement oscillation.** To quantitatively verify the longitudinal entanglement oscillation of \(|\Psi\rangle\), we performed an entanglement entropy analysis while digitally propagating the field. Using this approach, we determined the degree of entanglement \( E(\Psi, z) \in [0,1] \) as a function of \( k \_z + \varphi \). The respective experimental method is visualized in Fig. 2(c) (blue box) and (e).

Figure 4(a) shows typical intensity images obtained in experiments per \( z \)-distance and from which \( E \) is computed. The illustrated case corresponds to the scalar field shown in Fig. 4(b). Figures 4(b), (c) and (d) show the intensity values, normalized and arranged in the form of Table I. Here we show three cases: scalar, semi-vector and vector beam, with the corresponding values \( E = 0.01, 0.32 \) and 0.94, respectively. The complete set of experimental \( E \) values obtained as a function of the propagation distance \( z \) is presented in Fig. 5. Here, the
Our findings prove that by adjusting \( \phi \) and \( \Psi \), it is possible to engineer vector light fields whose degree of non-separability oscillates in free-space, from fully vector to scalar, as a function of the propagation distance, through spin-orbit coupling. While we have restricted ourselves to first-order vector vortex beams for the demonstration, the concept that we outline here is more general and can be applied to higher-order vortex modes as well as, in principle, any vector state with judicious choice of degree of freedom.

The surprising result is that our entanglement dynamics occur in free space under unitary conditions. We emphasize that while we have performed our experiments with coherent light for convenience, the same results are obtained for local entanglement of the internal degrees of freedom of a single photon. Neither theory nor experiments differentiate between these two cases, and thus, we address topical questions as to the notion of local and classical entanglement and its propagation dynamics.

An important aspect of this work is the practical approach to the generation and propagation of the fields. It is possible to engineer the desired effect using a Sagnac interferometer in which an input radially polarized vector beam is split into two beams that traveling along each arm: one of the beams is switched to azimuthal polarization, with a half-wave plate, and interfered with the radially polarized beam. In the third arm, both beams propagate in opposite directions while bearing orthogonal states of polarization, and thus generate a standing wave whose degree of entanglement varies along the propagation axis. This generating approach does not allow one to experimentally verify the spatially variant degree of entanglement. We offer a more powerful approach that utilizes digital generation and propagation enabled by an SLM. This approach allowed us to manipulate each vector beam independently and, among other options, perform digital propagation on each. Hence, both vector beams propagate in a colinear fashion in a manner that simulates propagation in opposite directions.

This approach of generation and propagation enabled us to realize any state of \( |\Psi\rangle \) with a chosen degree of entanglement that can be adapted in real time by simply changing the displayed hologram.

Importantly, this approach allows us not only to monitor the degree of non-separability but also to provide on-demand specific states to the observer’s positions. We believe that this method will enhance several noteworthy applications, namely, STED microscopy, optical trapping, quantum key distribution (QKD) and laser material processing systems, which we summarize diagrammatically in Fig. 6. For example, rapid changing of the mode type from circularly polarized light for cutting to radially polarized light for drilling would have clear benefits in processing materials with lasers\(^{17-19}\) while switching from a tight spot with radially polarized light to a donut beam with azimuthally polarized light (after an objective lens) is precisely the requirement for STED\(^{31-32}\). In addition, the presented configuration paves the way for novel QKD approaches using a prepare-and-measure BB84 QKD protocol, with vector and scalar OAM modes as the orthogonal and mutually unbiased bases\(^{47-48}\). This approach adds a new level of security to QKD protocols, since (as it has been noted to us) this work can be extended to a third dimension by considering the longitudinal mode function. Further, this tripartite description facilitates classical studies of GHZ-like states (see Supplementary Information), an exciting opportunity for further work with classically entangled states.

**CONCLUSIONS**

We have demonstrated that by exploiting complex modes of light, it is possible to have an oscillating degree of local entanglement during propagation, even though the medium is considered to be unitary, i.e., a medium in which the entanglement should not change. The result is a demonstration of spin-orbit coupling in paraxial light beams in free-space. We have shown this effect with entangled internal degrees of freedom of polarization and spatial
modes, and while our experiment was classical, the results hold equally well for local entanglement of the internal degrees of freedom of a single photon. In addition, we have demonstrated the concept behind the first tractor beam for local entanglement, which would be able to deliver a known degree of entanglement to some target plane. Our approach highlights intriguing questions about the notion of entanglement dynamics, opens a new topic in spin-orbit coupling and offers a new tool for a myriad of applications that would benefit from holographically controlled availability of vector and scalar states of light at the target plane.

MATERIALS AND CORRESPONDENCE

Correspondence and requests for materials should be addressed to C.R.G.

(b) Respective intensity $I_{R,L}$ of the $|R\rangle$ (red fit, black filled diamonds) and $|L\rangle$ (blue fit, black hollow diamonds) components of $|\Psi\rangle$, oscillating out of phase.

FIG. 6. Exemplary applications of virtually counter-propagated, orthogonally polarized vector modes: (a) adjusting the mode at the focal region for, e.g., STED microscopy systems, optical trapping or (b) laser material processing by digital propagation (phase shift $\varphi$), to create radially polarized beams for drilling and circularly polarized beams for cutting; (c) illustration of a novel quantum key distribution approach for the delivery of Alice’s states to Bob.

(a) \( |I_L\rangle \) and (b) \( |I_R\rangle \) for different phase shifts and electric fields.

(b) For different phase shifts and electric fields:
- \( \theta = -1 \) with \( E = 0.01 \)
- \( \theta = 0 \) with \( E = 0.32 \)
- \( \theta = \pi \) with \( E = 0.94 \)

(c) \( |I_L\rangle \) and (d) \( |I_R\rangle \) for different phase shifts and electric fields.

Scalar and vector states are shown with arrows.
